Key Words: BBN-RGD; PET; first-in-human; integrin $\alpha_v\beta_3$; GRPR; prostate cancer

This study aimed to document the first-in-human application of a $^{68}$Ga-labeled heterodimeric peptide BBN-RGD (bombesin-RGD) that targets both integrin $\alpha_v\beta_3$ and gastrin-releasing peptide receptor (GRPR). We evaluated the safety and assessed the clinical diagnostic value of $^{68}$Ga-BBN-RGD PET/CT in prostate cancer patients in comparison with $^{68}$Ga-BBN. Methods: Five healthy volunteers (4 men and 1 woman; age range, 28–53 y) were enrolled to validate the safety of $^{68}$Ga-BBN-RGD. Dosimetry was calculated using the OLINDA/EXM software. Thirteen patients with prostate cancer (4 newly diagnosed and 9 posttherapy) were enrolled. All the patients underwent PET/CT scans 15–30 min after intravenous injection of 1.85 MBq (0.05 mCi) per kilogram of body weight of $^{68}$Ga-BBN-RGD and also accepted $^{68}$Ga-BBN PET/CT within 2 wk for comparison. Results: With a mean injected dose of 107.3 ± 14.8 MBq per patient, no side effect was found during the whole procedure and 2 wk follow-up, demonstrating the safety of $^{68}$Ga-BBN-RGD. A patient would be exposed to a radiation dose of 2.90 mSv with an injected dose of 129.5 MBq (3.5 mCi), which is much lower than the dose limit set by the Food and Drug Administration. In 13 patients with prostate cancer diagnosed by biopsy, $^{68}$Ga-BBN-RGD PET/CT detected 3 of 4 primary tumors, 14 metastatic lymph nodes, and 20 bone lesions with an SUV$_{max}$ of 4.46 ± 0.50, 6.26 ± 2.95, and 4.84 ± 1.57, respectively. Only 2 of 4 primary tumors, 5 lymph nodes, and 12 bone lesions were positive on $^{68}$Ga-BBN PET/CT, with the SUV$_{max}$ of 2.98 ± 1.24, 4.17 ± 1.89, and 3.61 ± 1.85, respectively. Conclusion: This study indicates the safety and efficiency of a new type of dual integrin $\alpha_v\beta_3$– and GRPR-targeting PET radiotracer in prostate cancer diagnosis and staging.

Prostate cancer is the second most frequently diagnosed cancer in men and the fifth leading cause of death worldwide (1). Accurate diagnosis and staging of prostate cancer is of topmost importance for effective therapy, especially at the early stage (2). Currently, the only definitive way to confirm prostate cancer is through prostate biopsy (3). However, prostate biopsy is usually deemed necessary by considering several factors including family history, race, abnormal lumps within the prostate, and an elevated serum prostate-specific antigen level. MRI is one of the major modalities for image-guided diagnosis, but a certain portion of prostate cancer lesions might still be missed using MRI (4). In these patients, PET imaging with probes targeting various prostate cancer–specific markers will provide additional molecular information to facilitate lesion detection and staging (2).

Gastrin-releasing peptide receptor (GRPR) is an important biomarker used for prostate cancer diagnosis (5). Various GRPR-targeted imaging probes have been developed for noninvasive imaging of GRPR expression (6–8). Bombesin (BBN), an amphibian homolog of mammalian gastrin-releasing peptide (GRP), has been extensively used for imaging GRPR, after being labeled with various radionuclides (6,7,9–12). Several bombesin-related tracers have also been translated into the clinic for early phase studies (13–17). Previously, we have applied the GRPR-specific PET tracer $^{68}$Ga-NOTA-Aca-BBN(7-14) (denoted as $^{68}$Ga-BBN) for first-in-human studies in both healthy volunteers and patients with both low- and high-grade gliomas (18).

It has been found that both GRPR and integrin $\alpha\beta_3$ are overexpressed in neoplastic cells of human prostate cancer (19). To target both receptors, a heterodimeric peptide BBN-RGD was synthesized from bombesin(7-14) and c(RGDyK) through a glutamate linker and then labeled with $^{18}$F (20). Within this heterodimer, the RGD moiety binds to integrin $\alpha\beta_3$ receptor, which plays an important role in the regulation of tumor growth, angiogenesis, local invasiveness, and metastatic potential (21). In a PC3 xenograft model, $^{18}$F-FB-BBN-RGD had significantly higher tumor uptake.
than monomeric RGD and monomeric BBN peptide tracer analogs at all time points examined (20). A series of preclinical studies using the same strategy have confirmed several advantages of heterodimers including increased number of effective receptors, improved binding affinity, and pharmacokinetics (20,22–24).

In this study, for the first time, we translated BBN-RGD heterodimer into the clinic for the first-in-human study. The safety and dosimetry of 68Ga-BBN-RGD were evaluated in healthy volunteers. The preliminary diagnostic value of 68Ga-BBN-RGD PET/CT was also assessed in patients with primary or metastatic prostate cancer.

**MATERIALS AND METHODS**

**Radiopharmaceutical Preparation**

The macrocyclic chelator 1,4,7-triazacyclononane-N,N,N'-triaceitic acid (NOTA)–conjugated BBN-RGD was synthesized according to a method described in our previous publication (22). 68Ga was eluted from a 68Ge/68Ga generator (ITG) using 0.05 M HCl and mixed with 1.25 M NaOAc buffer to adjust pH to 4.0. Radiolabeling of BBN-RGD was performed in a sterile hot cell. The radiochemical purity of the product 68Ga-BBN-RGD exceeded 97%. 68Ga-BBN was synthesized following a procedure reported previously (18).

**Subject Enrollment**

This clinical study was approved by the Institutional Review Board of Peking Union Medical College Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College. All subjects signed a written informed consent form. Five healthy volunteers (4 men and 1 woman; mean age ± SD, 45.2 ± 9.9 y; age range, 28–53 y; mean weight ± SD, 66.6 ± 8.3 kg; weight range, 55–74 kg) were included in the study. Exclusion criteria consisted of conditions of mental illness, severe liver or kidney disease with serum creatinine greater than 3.0 mg/dL (270 μM), or any hepatic enzyme level 5 times or more than normal upper limit. Participants were also excluded if they were known to have severe allergy or hypersensitivity to intravenous radiographic contrast or claustrophobia during PET/CT scanning or if they were pregnant or breast-feeding.

A total of 13 patients with prostate cancer (age range, 49–70 y; mean age, 62.4 ± 6.0 y), of which 4 patients were newly diagnosed as having prostate cancer by sextant core-needle biopsy and 9 patients underwent prostatectomy or brachytherapy, were enrolled with written informed consent. The inclusion criteria were being between 40 and 80 y old, having a prostate neoplasm identified by ultrasound or MRI, being diagnosed by needle biopsy as having prostate cancer by sextant core-needle biopsy and had not received any prior therapy and 9 patients underwent prostatectomy or brachytherapy, 4 patients were newly diagnosed as having prostate cancer by sextant core-needle biopsy and consented to participate in the study. The safety and dosimetry of 68Ga-BBN-RGD were evaluated in healthy volunteers. The preliminary diagnostic value of 68Ga-BBN-RGD PET/CT was also assessed in patients with primary or metastatic prostate cancer.

**Radiopharmaceutical Preparation**

The macrocyclic chelator 1,4,7-triazacyclononane-N,N,N'-triaceitic acid (NOTA)–conjugated BBN-RGD was synthesized according to a method described in our previous publication (22). 68Ga was eluted from a 68Ge/68Ga generator (ITG) using 0.05 M HCl and mixed with 1.25 M NaOAc buffer to adjust pH to 4.0. Radiolabeling of BBN-RGD was performed in a sterile hot cell. The radiochemical purity of the product 68Ga-BBN-RGD exceeded 97%. 68Ga-BBN was synthesized following a procedure reported previously (18).

**Image and Data Analysis**

A Siemens MMWP workstation was used for postprocessing. Visual analysis was used to determine the general biodistribution and the temporal and intersubject stability. The volume of interest of normal organs/tissues and concerned lesions were drawn on the axial images. The radioactivity concentration and SUV in the volumes of interest were obtained through the software.

For the volunteers, the dosimetry calculation was performed according to the EANM Dosimetry Guidance (25) and calculated using OLINDA/EXM (version 1.1; Vanderbilt University) with the procedure reported in a previous study (18). The void time of the bladder was set as 60 min. The absorbed doses were calculated by entering the time-integrated activity coefficient for all source organs into OLINDA/EXM for either a 73.7-kg adult man or a 56.9-kg adult woman.

For the patients, regions of interest were drawn manually on the site of lesions using a 3-dimensional ellipsoid isosurface on each image with the assistance of the corresponding CT images by 2 experienced nuclear medical physicians. The results were expressed as SUVmean and SUVmax.

**99mTc-MDP Bone Scanning**

For the patients, bone scan images were obtained using a dual-head Siemens SPECT scanner. Planar images of the whole-body skeleton were acquired in the anterior and posterior views 3 h after intravenous injection of 925 MBq (25 mCi) of 99mTc-MDP.

**Immunohistochemical Staining**

Representative tumor and lymph node samples were fixed with 10% neutral buffered formalin and embedded in paraffin. After blocking and washing, 5-μm-thick tissue sections were incubated with mouse antibody monoclonal antibody against human GRPR (PA5-256791; Thermofisher scientific) and integrin αvβ3 (1:200, sc-7312; Santa Cruz Biotechnology), respectively. Six fields were randomly selected from each section and observed using a light microscope (BX41; Olympus). For semiquantification of GRPR and integrin αvβ3 expression, 5 entire high-power fields (×400) containing clusters of malignant cells
were identified randomly per slide and scored for intensity and percentage of GRPR and integrin \( \alpha_v \beta_3 \) staining expression. The procedure was repeated by 2 independent experienced examiners.

**RESULTS**

*Safety*

No adverse events or serious adverse events occurred after \(^{68}\)Ga-BBN-RGD injection for all the healthy volunteers and the patients, and no obvious changes in vital signs or clinical laboratory tests were found before and after the injection of \(^{68}\)Ga-BBN-RGD. For the patients, 1.85 MBq (0.05 mCi) of \(^{68}\)Ga-BBN-RGD per kilogram of body weight were injected intravenously. The median and maximum injected dose was 123.7 \( \pm \) 11.5 MBq and 146.2 MBq, respectively. The median and maximum injected mass was 12.3 \( \pm \) 2.6 mg and 15 mg, respectively.

*Biodistribution and Dosimetry*

After intravenous administration, \(^{68}\)Ga-BBN-RGD showed rapid clearance through the kidneys with 49.9\% \( \pm \) 10.2\% of total injected radioactivity observed in the urine at 30 min after injection. The pancreas also had high accumulation, with an \( \text{SUV}_{\text{mean}} \) of 10.96 \( \pm \) 1.10 at 30 min after injection, which is in line with the known high-level expression of GRPR in the pancreas (26). The liver and spleen showed moderate uptake, with an \( \text{SUV}_{\text{mean}} \) of 1.54 \( \pm \) 0.24 and 1.80 \( \pm \) 0.46, respectively. Low background activities in the brain, lung, and muscle were found with \( \text{SUVs} \) of 0.16 \( \pm \) 0.05, 0.44 \( \pm \) 0.11, and 0.40 \( \pm \) 0.16, respectively (Supplemental Table 1 [supplemental materials are available at http://jnm.snmjournals.org]; Fig. 1).

The estimated absorbed dose of \(^{68}\)Ga-BBN-RGD for each organ derived from PET/CT images of healthy volunteers is shown in Table 2. Because of the high accumulation of radioactivity in the urinary bladder, the urinary bladder wall had the highest absorbed dose of 0.33 \( \pm \) 0.16 mSv/MBq, which was followed by the kidneys (0.0647 \( \pm \) 0.0436 mSv/MBq) and pancreas.

![Figure 1](image-url)
The average and maximum SUVs of all the lymph node metastatic lesions were $3.77 \pm 1.65$ and $6.26 \pm 2.95$ at 30 min after injection, respectively. The average and maximum SUVs of all the bone lesions were $3.01 \pm 0.84$ and $4.84 \pm 1.57$ at 30 min after injection, respectively. Only 5 lymph node metastases and 12 bone lesions were detected by $^{68}$Ga-BBN PET/CT, with significantly lower average and maximum SUVs ($2.79 \pm 1.19$ and $4.17 \pm 1.89$ for lymph nodes and $2.26 \pm 1.15$ and $3.61 \pm 1.85$ for bone lesions at 30 min after injection, $P < 0.05$) (Figs. 3 and 4).

In comparison, MRI detected all the 14 lymph nodes in the pelvic cavity. However, only 5 bone lesions located in the ilium, pubis, rib, and thoracic and lumbar vertebrae were detected by MRI. Eleven of 20 lesions identified by $^{68}$Ga-BBN-RGD PET/CT showed positive signal with MDP bone scanning. Besides these 20 lesions, 14 abnormal hotspots were shown on MDP SPECT bone scanning. These hotspots were confirmed as benign lesions by MRI and history such as traumatic fracture, vertebral degeneration, and spinal stenosis (Fig. 5).

**DISCUSSION**

$^{68}$Ga-BBN-RGD was found to be safe and well tolerated in all healthy volunteers and recruited patients, with no adverse events occurring after tracer injection. With a typical 130 MBq (3.5 mCi) injected activity of $^{68}$Ga-BBN, the whole-body effective dose is 2.90 mSv, which is much lower than the dose limit set by the Food and Drug Administration (27). All these data confirmed the safety of $^{68}$Ga-BBN for further clinical applications.

One major advantage of heterodimer over the corresponding monomers is the multivalency effect, resulting in improved binding affinity and increased number of effective receptors (20, 22–24). Consistently, both $^{68}$Ga-BBN-RGD and $^{68}$Ga-BBN showed uptake in the primary prostate tumors that were either

(0.0523 ± 0.0173 mSv/MBq). The total effective dose equivalent and effective dose were 0.0321 ± 0.0138 and 0.0223 ± 0.0093 mSv/MBq, respectively.

**Detection of Primary Prostate Cancer**

For the 4 patients with primary prostate cancer, $^{68}$Ga-BBN-RGD PET/CT showed positive findings in 3 lesions (75%). The primary lesions were diagnosed by MRI, and the diagnosis was confirmed by needle biopsy. The SUV$_{\text{mean}}$ and SUV$_{\text{max}}$ were 3.26 ± 0.52 and 4.46 ± 0.50, respectively. Two of the 4 lesions were positive on $^{68}$Ga-BBN PET/CT, with the average mean and maximum SUVs of 2.09 and 2.98, respectively (Fig. 2). To further elucidate the findings from PET, we performed immunohistochemical staining against GRPR and integrin αvβ3 with the biopsy samples. As shown in Figure 3, both GRPR- and integrin-positive staining were found in 2 patients, GRPR-negative and integrin αvβ3-positive staining in 1 patient, and both GRPR- and αvβ3-negative staining in 1 patient.

**Detection of Lymph Node and Bone Metastasis**

For all the 13 patients with prostate cancer, $^{68}$Ga-BBN-RGD PET/CT detected 14 metastatic lymph nodes and 20 bone lesions.
GPRR-positive or integrin $\alpha_v\beta_3$-positive. However, $^{68}$Ga-BBN failed to visualize the lesions that were GPRR-negative and integrin $\alpha_v\beta_3$-positive whereas $^{68}$Ga-BBN-RGD showed positive results in these cases. It is also reasonable that both tracers had negative results in the lesion with neither GRPR nor integrin $\alpha_v\beta_3$ overexpression, implying that $^{68}$Ga-BBN-RGD PET/CT is specific for GRPR and integrin $\alpha_v\beta_3$. Because of the limited size of the patient population, the frequency of prostate cancer tumors both GRPR-negative and integrin $\alpha_v\beta_3$-negative cannot be determined in this study and will need further investigation.

With a receptor binding assay in specimens of primary prostate cancer, 37% of samples showed negative bombesin binding (28). Thus, it is foreseeable that $^{68}$Ga-BBN-RGD PET will increase the detection rate of primary prostate cancer.

About 40%–60% of men with prostate cancer have lymph node involvement or extracapsular disease at the time of presentation, and 70% develop lymph node metastasis during the course (29). Although treatable at the early stage, prostate cancer is prone to metastasize; an effective and specific imaging method of detecting both primary and metastatic lesions is thus of critical importance to manage patients with prostate cancer. In 3 patients with LN metastasis, $^{68}$Ga-BBN-RGD PET/CT identified all 14 metastasized LNs as MRI did, which is dramatically better than $^{68}$Ga-BBN PET/CT. Durkan et al. (30) proposed that prostate cancer cells differentially express specific receptors depending on factors such as chronicity and metastatic nature. Thus, compounds capable of targeting more than one biomarker would have the ability of...
binding to both early and metastatic stages of prostate cancer, creating the possibility for a more prompt and accurate diagnostic profile for both the primary and the metastatic tumors. This may partially explain our results that 68Ga-BBN-RGD PET/CT is better than 68Ga-BBN PET/CT in detecting metastasized LNs.

Autopsy studies suggest that approximately 80%–90% of prostate cancer patients have bone metastasis at death although only 6% of men with prostate cancer have metastatic disease at diagnosis (31). Skeletal metastasis of prostate cancer is routinely assessed by 99mTc-MDP bone scanning for the staging of prostate cancer. 99mTc-MDP bone scanning is sensitive but lacks specificity because localized skeletal accumulation of 99mTc-MDP can be observed in the case of trauma and infection. Thus, 99mTc-MDP bone scanning may not be recommended in asymptomatic patients if the serum prostate-specific antigen level is less than 20 ng/mL in the presence of well-differentiated or moderately differentiated tumors (3). In this study, 68Ga-BBN-RGD PET/CT detected 20 bone lesions in 7 patients either with primary prostate cancer or after radical prostatectomy. Eleven of these 20 lesions showed positive signal on 99mTc-MDP bone scanning, and only 5 of these lesions were detectable with MRI. More importantly, the patients with bone metastases do not necessarily have an elevated prostate-specific antigen level (Table 1).

Bisanz et al. (32) have illustrated a positive role of αv integrins on prostate tumor survival in the bone. Integrin αvβ3 activation on tumor cells is essential for the recognition of key bone-specific matrix proteins, suggesting that the αvβ3 integrin modulates prostate cancer growth in distant metastasis (33). In a recently published clinical study in prostate cancer patients using 18F-galacto-RGD PET, 58 of 74 bone lesions were identified, with a detection rate of 78.4% (34). Thus, RGD molarity in 68Ga-BBN-RGD may play a major role in bone metastasis detection. However, 1 limitation of this study is the lack of histologic confirmation of the detected bone metastasis. Thus, the GRPR and integrin αvβ3 expression status in these metastases are unknown. In addition, the accurate diagnostic and prognostic value of 68Ga-BBN-RGD warrants further larger scale clinical investigations.

Besides BBN-based imaging probes, various PET tracers have been used for the detection of prostate cancer such as 18F-FDG, 11C-choline or 18F-fluorocholine, 11C-acetate, 18F-FACBC, and prostate-specific membrane antigen targeting agents (35). Each of these tracers has advantages and limitations because of the heterogeneity of the disease. We expect 68Ga-BBN-RGD to play an additive role in staging and detecting prostate cancer and provide guidance for internal radiotherapy using the same peptide labeled with therapeutic radionuclides.

CONCLUSION

This study indicates the safety and the efficacy 68Ga-BBN-RGD, a heterodimeric PET tracer targeting both GRPR and integrin αvβ3. 68Ga-BBN-RGD PET/CT would have great value in discerning both primary prostate cancers and metastases in lymph nodes and skeleton, providing tumor staging information and monitoring response of bone metastases to therapy.
